Job polarization
Routine-biased technical change
Business cycle
Human capital investment
Great Recession

A B S T R A C T

Recent empirical evidence suggests that skill-biased technological change accelerated during the Great Recession. We use a neoclassical growth framework to analyze how business cycle fluctuations interact with a long-run transition towards a skill-intensive technology. In the model, the adoption of new technologies by firms and the acquisition of new skills by workers are concentrated in downturns due to low opportunity costs. As a result, shocks lead to deeper recessions, but they also speed up adoption of the new technology. Our calibrated model matches both the long-run downward trend in routine employment and key features of the Great Recession.

1. Introduction

Over the last couple of decades rapid advances in information technology, electronics and robotics have made many jobs associated with relatively simple and repetitive tasks obsolete, as they can now be easily performed by machines. While these routine jobs have been disappearing, employment in non-routine cognitive occupations (e.g., programmers or financial analysts) and non-routine manual jobs (mainly in low-skill services), has been increasing. Both of these types of occupations are associated with tasks that have proved harder to automate, at least thus far.\footnote{We thank Henry Siu (discussant), Sevin Yeltekin (editor), seminar participants at Columbia, Wharton, and conference participants at the Carnegie-Rochester-NYU Conference on Public Policy, for which this paper was prepared.}

In a recent contribution, Jaimovich and Siu (2015) (JS hereafter) show that this job polarization process accelerates during recessions. Over the last thirty years, employment in routine occupations experienced significant drops during economic downturns and, unlike for other types of jobs, these drops were not followed by subsequent recoveries. Strikingly, 88% of job losses in routine occupations since the mid-1980s happened during the three downturns that occurred over this span

of time. In contrast, non-routine jobs experienced only small declines during these recessions, and rapidly recovered afterwards. Importantly, these patterns began during the mid-1980s, when the pace of innovation in automation technologies accelerated (e.g., see Eden and Gaggli, 2018). In prior decades, routine employment bounced back quickly as economy recovered.

We build a quantitative model to better understand these patterns, and to evaluate their importance for macroeconomic fluctuations and technology adoption. In the model, consumption goods are produced using manual services and intermediates. The manual services employ low-skill workers to perform non-routine manual tasks. Production of intermediates, in contrast, is more complex and requires a combination of non-routine cognitive tasks, performed by high-skill workers, and routine tasks, performed by low-skill workers, similarly to Autor and Dorn (2013). While only one technology is available to produce manual services, firms can choose either an "old" or a "new" technology to produce intermediates. The new technology is more skill-intensive than the old one, and it becomes better over time due to continued improvements in information technologies and automation (Autor et al., 2003). As a result, firms progressively switch from the old to the new technology, and non-routine cognitive employment goes up as a result. Moreover, since manual services and intermediates are complements, non-routine manual employment also increases. The slow improvement in the productivity of the new technology therefore generates patterns of job polarization similar to those visible in the data.

Adopting the new technology is costly, both in terms of factors of production that must be used to reorganize the firm and in terms of the profits that are lost during the reorganization. As a result, firms in our model prefer to adopt the new technology during recessions, when factors of production are cheap and the loss in foregone profits is minimized. Recessions are also periods of skill acquisition by workers. Since wages are depressed, low-skill workers take advantage of the low opportunity costs to acquire the new skills, which will be in high demand once the firms begin using the new technology towards the end of the recession. Together, the adoption of new technology by firms and the acquisition of skills by workers take resources away from production during downturns and, as a result, amplify the effect of negative business cycle shocks. At the same time, this short-run pain creates long-lasting value in the form of a better production technology and a higher skill level.

The patterns of technology adoption and skill acquisition generated by the model have support in the data. The evidence from the Great Recession is particularly telling. Indeed, while the recession was accompanied by a decline in routine employment, post-secondary education enrollment increased markedly over the same period. At the same time, while aggregate investment fell massively, investment in new equipment and software technology was mostly unaffected or slowed down only slightly. Worldwide sales of industrial robots increased sharply as the recession ended, indicating increased adoption of the new automation technology.

The model is calibrated to match standard real business cycle moments and the overall increase in the employment share of non-routine cognitive workers. Importantly, for a reasonable level of complementarity between intermediates and manual services, the model is able to explain the recent growth in the employment share of non-routine manual labor, as well as the decline in routine manual jobs. When fed with a large negative TFP shock that corresponds to the Great Recession in both its magnitude and its timing (relative to the process of technological transition), the model is able to replicate the sharp drop in the share of routine workers in the labor force that occurred between 2008 and 2010. We also show that even in the counterfactual scenario in which the economy does not suffer the Great Recession the smooth process of technological transition still delivers the employment share of routine manual workers that is observed empirically in 2012. Thus, while the Great Recession may have accelerated the process of job polarization, it does not seem to have contributed substantially to its long-term trend.

Literature review

We model technological progress as involving a change in the production function, reminiscent of the general-purpose technology literature (e.g., Helpman, 1998). The new technology is relatively more high-skill-intensive, similar to Heckman et al. (1998) and Goldin and Katz (1998). Relatedly, Buera et al. (2015) also hypothesize that the share of high-skill labor in production function has increased as a result of the recent technological change. An alternative approach would be to use the notion of capital-skill complementarity, as proposed by Griliches (1969) and Krusell et al. (2000). There, technological progress makes capital equipment more productive and cheaper, causing increase in demand for the high skill.

In our model, technology adoption requires both time and resources. In this regard, it is similar to Jovanovic and MacDonald (1994), Andolfatto and MacDonald (1998) and, especially, to Greenwood and Yorukoglu (1994) who assume that high-skill labor is essential to adopt new technologies.

In a “pit stop” model of technology adoption, which is reminiscent of the Schumpeterian view of recessions, periods of depressed economic activity are used by firms to reorganize production or invest in organizational capital (e.g., Hall, 1991, Cooper and Haltiwanger, 1993, Aghion and Saint-Paul, 1998, and Caballero and Engel, 1999). Recently, these ideas have been brought to explain anemic employment recoveries following the three latest recessions (van Rens, 2004, Koenders and Rogerson, 2005, and Berger, 2012). Our work is also related to Restrepo (2015) who builds a model in which skill mis-

---

2 Schumpeter (1934) considers recessions as “industrial mutation that incessantly revolutionizes the economic structure from within, incessantly destroying the old one, incessantly creating a new one”. Caballero and Hammour (1994) study how the process of creative destruction interacts with business cycles.
match can lead to a prolonged adjustment process following a structural shock as firms struggle to find workers with the appropriate skills for new jobs.

Training is modelled in the spirit of real business cycle models augmented with human capital accumulation as in Perli and Sakellaris (1998) and Dejong and Ingram (2001). As a result, in our model investment in human capital also increases during recessions. Counter-cyclical investment in education is a well-established fact in the empirical literature (see, among many others, Dellas and Sakellaris, 2003, Charles et al., 2015, and Barr and Turner, 2015).

The remainder of the paper is organized as follows. Section 2 discusses recent empirical evidence on the interaction between routine-biased technological change and recessions. Section 3 describes the model. The model is calibrated in Section 4. Section 5 contains quantitative exercises. Section 6 concludes.

2. Empirical evidence

In this section, we discuss empirical evidence on the interaction between recent downturns and the speed of job polarization. We then show that some forms of investment in skill-complementary capital (e.g., software and information processing equipment), are only mildly pro-cyclical, in contrast with very pro-cyclical investment in structures. We use this evidence to help motivate our model, in which adoption of a new skill-intensive technology requires reorganization of the firm that disrupts production and is therefore more attractive during periods of low opportunity costs. At the same time, workers use recessions to invest in their human capital in order to satisfy the increasing demand for skill, which results in accelerated job polarization.

A large empirical literature documents that job polarization, induced by routine-biased technological change, was accelerated by the recent recessions. Hershbein and Kahn (2018) show that demand for high-skill workers rises in metropolitan statistical areas with lower employment growth. This “upskilling” effect is long lasting and does not disappear even when labor market recovers. Moreover, firms that upskill more actively also invest more. Restrepo (2015) documents a dramatic negative impact of the Great Recession on routine cognitive jobs. Anghel et al. (2014) argue that the Great Recession sped up job polarization in Spain. Zhang (2015) finds that during crises firms intensive in routine labor reduce routine employment and invest more in machines. Using a panel of Spanish manufacturing firms, Aguirregabiria and Alonso-Borrego (2001) show that firms’ decisions to reorganize production is counter-cyclical and lead to a significant shift in occupation structure towards white-collar jobs.

Most relevant for our purpose, JS argue that the three recent recessions affected routine and non-routine workers in a dramatically different way. They show that routine employment generally drops more during recessions than non-routine employment. In addition, the three recent recessions are accompanied by no recovery in routine employment at all. Since the 1980s, per capita routine employment has been falling, not only as a fraction of total employment, but also in absolute terms. JS therefore refer to the mid-1980s as the start of the job polarization era.

The job polarization era is also marked by an overall drop in labor force participation and an increase in post-secondary education enrollment. As shown in Fig. 1, labor force participation has been declining since the end of 1990s. Recessions appear to be important drivers of this decline. In particular, labor force participation fell from 66 to 63% following the Great Recession. At the same time, post-secondary education enrollment was almost flat from the mid 1970s up to the mid-1990s.

---

3 Using FRED data, JS define routine occupations as “sales and related occupations”, “office and administrative support occupations”, “production occupations”, “transportation and material moving occupations”, “construction and extraction occupations”, and “installation, maintenance, and repair occupations”. Non-routine cognitive occupations include “management, business, and financial operations occupations”, “professional and related occupations”, “Service occupations” are non-routine manual. We use their classification in our numerical analysis. See their paper for more details about classification and robustness.
but increased afterwards, with a pronounced spike around the Great Recession.\footnote{4} In our model, both the decreasing labor force participation and the increasing education enrollment are driven by the adoption of the skill-intensive technology.

Recessions also have differential effects on different types of investment. For example, a pronounced persistent decline in private investment that happened in the aftermath of the Great Recession is to a large extent driven by an unprecedented drop in residential investment. In contrast, as shown in Fig. 2, investment in intellectual property, such as software and R&D, as well as industrial and information processing equipment, tools that are used by skill-intensive firms, experienced a much smaller drop and recovered rapidly (see also Brynjolfsson and McAfee, 2012). In Supplementary Appendix it is also shown that world-wide shipments of industrial robots experienced a sharp increase immediately after the Great Recession.

3. Model

Time is discrete and goes on forever, $t = \{0, 1, \ldots \}$. The economy is populated by a representative household that consists of a unit measure of workers. A worker is either low-skill or high-skill, and a low-skill worker can become high-skill through training.\footnote{5} On the production side, a final good is produced with two kinds of inputs. The first one is “manual services,” which can be produced using low-skill labor in non-routine manual tasks. The second input is “intermediates,” which can be produced by combining capital and the two types of labor.\footnote{6}

Intermediates can be produced using one of two different technologies: an old technology that is low-skill intensive and a new technology that is high-skill intensive. All firms begin in period $t = 0$ by using the old technology and, as the productivity of the new technology slowly improves, progressively switch to it. Adopting the new technology requires capital and high-skill labor, and the firm must stop production while the workplace is being reorganized. Below we describe the agents in greater detail.

3.1. Representative household

The representative household values final consumption goods using a constant relative risk aversion utility function with coefficient $\gamma$ and discounts future utility at a rate $b$. The household consists of a unit mass of atomistic workers, each endowed with one unit of labor. A fraction $h$ of them are high-skill and the remaining $u = 1 - h$ are low-skill. Low-skill workers can either work in production ($u_p$), in which case they earn a wage $w_h$, or go to school as students ($u_s$) in order to be trained and eventually become high-skill workers. While in training, low-skill workers are out of the labor force. High-skill workers are always employed, either in production ($h_p$) for a wage $w_h$, or in schools as teachers ($h_t$). The household also owns the capital stock $k$ and either uses it to train workers ($k_s$) or rents it out to firms for production ($k_p$) at a rate $r$.

Each period, the abilities of a fraction $\delta_h$ of high-skill workers are rendered obsolete and they become low-skill. The dynamics of the mass of high-skill workers is

$$h' = (1 - \delta_h)h + \phi(k_s, h, u_s), \quad h' \in [0, 1],$$

where $\phi(k, h, u)$ is the training technology. As in Perli and Sakellaris (1998), we assume that

$$\phi(k, h, u) = sk^\beta (\mu_s h^\rho + (1 - \mu_s)u^\rho) \frac{1}{1-k},$$

\footnote{4} Correlation between the labor force participation and the post-secondary enrollment ratio seems to change sign around the start of the job polarization era. Between 1963 and 1984 the correlation is 0.84, while between 1985 and 2014 it is −0.63.

\footnote{5} It is worth noticing that enrolled in post-secondary institutions do not necessarily complete their education. Thus, the dynamics of post-secondary enrollment and completion ratios might be different.

\footnote{6} In the model, high skill is related to ability to implement non-routine cognitive tasks and not directly to education level. Although the two are doubtless positively correlated, they are not the same (see JS for a discussion). Nevertheless, as discussed in Section 4, post-secondary education data is used for the calibration purposes.

\footnote{7} Our definition of two different inputs is similar to Autor and Dorn (2013). It distinguishes between two broad types of tasks implemented by low-skill workers. Routine occupations required to produce intermediates are relatively easy to automate or offshore (e.g., secretaries, paralegals, laborers). Non-routine manual occupations in manual services, such as janitors or barbers, are not.
where $\beta_s$ is the capital intensity of the training sector, $\mu_s$ is the high-skill intensity and $\rho_s$ relates to the elasticity of substitution between high-skill and low-skill workers (teachers and students).

The household owns the firms and receives their profits $\Pi$ every period. It also invests in new capital subject to quadratic adjustment costs $\varphi(i, k) = i \frac{1}{2} (1 - \delta k)^2 k$. Capital depreciates at a rate $\delta$, so that its law of motion is

$$k' = (1 - \delta k) k + i.$$  

(3)

Denoting by $\Omega$ the aggregate state of the economy (which will be fully described later), the dynamic problem of the household is

$$W(h, k, \Omega) = \max_{h', k, h_p, u, u_p, k_p} e^{\xi - r} \mathbb{E} \left[ W(h', k', \Omega') | \Omega \right]$$  

subject to the budget constraint

$$c + i + \varphi(i, k) = w_h(\Omega) \cdot h_p + w_u(\Omega) \cdot u_p + r(\Omega) \cdot k_p + \Pi(\Omega),$$  

(5)

and the laws of motion (1) for high-skill workers and (3) for capital and to an aggregate law of motion $\Omega' = G(\Omega)$ for $\Omega$.

3.2. Firms and technologies

On the production side, the final good is produced by combining two inputs: intermediates and manual services. Manual services are produced by low-skill workers in non-routine manual jobs. Intermediates can be produced by either the new or the old technology, which both require high-skill and low-skill workers in non-routine cognitive and routine tasks, respectively. Final goods producers combine the two inputs into the final good, which is then consumed by the household.

3.2.1. Final goods producer

There is a competitive industry that produces the final consumption good by combining intermediates (from both old and new firms) with manual services. The price of the final good is normalized to 1. The static problem of a firm in this industry is

$$\max_{y_n, y_m} e^{\mu} \left[ (y_{i,n} + y_{i,0})^\delta + y_{ms}^\delta - P_b(\Omega)y_{i,n} - P_n(\Omega)y_{i,0} - B_i(\Omega)y_{ms} \right],$$  

(6)

where $y_{i,n}$ is the amount of intermediates produced with the new technology, $y_{i,0}$ is the amount of intermediates produced with the old technology and $y_{ms}$ is the input flow from manual services.\(^8\)

In the spirit of endogenous growth models a-la Romer (1990) and Grossman and Helpman (1991), we assume that the new technology allows intermediate firms to produce a potentially different variety of goods, implying imperfect substitutability between the two ($\theta < 1$). This assumption captures the fact that new labor-saving technologies often do not fully replace the products of old technologies. While digital sound has become much more wide-spread than its analog counterpart, demand for LPs is still nontrivial, as some music connoisseurs prefer the latter. Locally-grown organic foods are not fully substituted away by genetically modified products. Importantly, however, our results generally extend to the case of perfect substitutability, $\theta = 1$, as shown in the Supplementary Appendix.

Aggregate total factor productivity $z$ follows an AR(1) process such that

$$z' = \rho z + \sigma_\epsilon \epsilon_\epsilon', \text{ where } \epsilon_\epsilon \sim \text{iid } N(0, 1).$$  

(7)

3.2.2. Intermediates producers

There is a unit mass of atomistic intermediates producers. These firms can operate using either the old or the new technology, indexed by $j = \{0, n\}$. We refer to firms currently operating each technology as "old firms" and "new firms," respectively. Firms combine capital $k$, high-skill labor $h$ and low-skill labor $u$ using the following production functions:

$$F_j(\mu_j, h, u, k) = A_j k^{\beta} (h^{\mu_1 u^{1-\mu_1} j^{1-\beta}} \cdot j = \{0, n\},$$  

(8)

where $\beta$ is capital intensity, $A_j$ is total factor productivity, $\mu_j$ captures the skill intensity of the production function, and $\alpha < 1$ is the decreasing returns to scale parameter. $\pi_j$ denotes the profits of a firm operating technology $j$ so that

$$\pi_j(\Omega) = \max_{h, u, k} P_j(\Omega) F_j(\mu_j, h, u, k) - w_h(\Omega) \cdot h - w_u(\Omega) \cdot u - r(\Omega) \cdot k,$$  

(9)

where $P_j(\Omega)$ is the price of intermediates of type $j$.

The old and the new technology differ in two ways. First, the new technology is relatively more high-skill-intensive than the old one ($\mu_n > \mu_0$). Second, their productivities are different ($A_n \neq A_0$). At $t = 0$ the new technology is not available ($A_n = 0$) and all agents consider its arrival as a zero-probability event. All firms are using the old technology. Over time,

---

8 We implicitly assume that the share parameters in the CES aggregators in (6) are equal to 1. This is without loss of generality given our calibration of the relative productivities of the three technologies.
technological progress favors the new technology such that $A_n$ grows faster than $A_p$. This induces firms to switch from the old to the new technology. Since the new technology is more high-skill intensive, technological adoption increases the demand for high-skill workers, which puts upward pressure on their wages. As a result, more low-skill workers enter the training process and the overall skill level in the economy increases. Without loss of generality, in what follows $A_o$ is normalized to 1.

Switching from the old to new technology is costly and risky. A firm that attempts to switch does not produce during the current period and successfully acquires the new technology with probability $\xi(h, k)$, $\xi \in [0, 1]$, $\xi_{hh}, \xi_{kk} < 0 < \xi_h, \xi_k$. A firm can increase its odds of successful adoption by hiring more high-skill workers $h$ or by renting more capital $k$.\textsuperscript{9} Following Andolfatto and MacDonald (1998), the probability of successful adoption is

$$\xi(h, k) = 1 - \exp(-\eta k^{\beta_h} h^{1-\beta_h}).$$  \hspace{1cm} (10)

Since a new firm never switches back to the old technology, its value is simply

$$V_n(\Omega) = \pi_n(\Omega) + \mathbb{E}[M(\Omega, \Omega')V_n(\Omega')|\Omega],$$  \hspace{1cm} (11)

where $M(\Omega, \Omega')$ is the stochastic discount factor of the representative household.

In contrast, an old firm must decide each period whether to attempt a technology switch or to continue producing using its current technology. As a result, its value is

$$V_o(\Omega) = \max\left\{V_o^p(\Omega); V_o^a(\Omega)\right\},$$  \hspace{1cm} (12)

where the value of production is

$$V_o^p(\Omega) = \pi_o(\Omega) + \mathbb{E}[M(\Omega, \Omega')V_o(\Omega')|\Omega],$$  \hspace{1cm} (13)

and the value of attempting to adopt the new technology is

$$V_o^a(\Omega) = \max_{h,k} \left\{-w_h(\Omega)h - r(\Omega)k + \xi(h, k)\mathbb{E}[M(\Omega, \Omega')V_n(\Omega')|\Omega]\right\} + (1 - \xi(h, k))\mathbb{E}[M(\Omega, \Omega')V_o(\Omega')|\Omega].$$  \hspace{1cm} (14)

In what follows, we denote the masses of producing new and old firms by $m_n$ and $m_o$, respectively. The remaining fraction, $1 - m_n - m_o$, are in the adoption process and are therefore not producing.

3.2.3. Manual services producer

There is a competitive representative firm producing manual services using low-skill workers. As in Autor and Dorn (2013), its production function is $f_{ms}(u) = A_{ms}u$ such that it maximizes

$$\max_u p_{ms}(\Omega)f_{ms}(u) - w_u(\Omega)u,$$  \hspace{1cm} (15)

where $p_{ms}(\Omega)$ is the price of services.

3.3. Competitive equilibrium

The set of aggregate state variables $\Omega$ contains the aggregate capital stock $K$, the mass of high-skill workers $H$, the mass of firms producing intermediates which operate the new technology $m_n$, the productivity of the new technology $A_n$, and the productivity of the final goods producer $z$. A competitive equilibrium in this economy is defined below.\textsuperscript{11}

**Definition 1.** A recursive competitive equilibrium is a collection of value functions for the firms $V_o, V_o^p, V_o^a, V_n$ and for the household $W$, and their associated optimal decisions; a collection of prices $w_h, w_u, r, p_o, p_n, P_{ms}$ and aggregate laws of motion $G$, such that (1) the value functions and the optimal decisions solve problems (4), (6), (11), (12) and (15); (2) the markets for high-skill and low-skill labor and the market for capital clear:

$$H_p = m_nh_n + m_oh_o + (1 - m_n - m_o)h_d,$$  \hspace{1cm} (16)

\textsuperscript{9} We assume that the technology adoption has a probabilistic nature to capture, in a tractable way, that the adoption process might be longer than one period of the model, which is taken to be one year. Brynjolfsson et al. (1994) and Brynjolfsson and Hitt (2003) find that it takes several years for a firm to fully adopt computer technology.

\textsuperscript{10} The importance of high-skill labor (e.g., management and IT consultants) for technology adoption is emphasized by Nelson and Phelps (1966) and Greenwood and Yorukoglu (1994).

\textsuperscript{11} Since the competitive economy is efficient, we solve the problem of a social planner maximizing the welfare of the representative household. Given the complexity of the economy, the model is solved using a perfect foresight approach. In particular, all business cycle shocks are assumed to be completely unexpected. To verify the validity of this approach, we have also solved a simpler version of the fully stochastic model globally. The perfect foresight approach does not alter the predictions of the model but significantly decreases the complexity of the computations. The role of a potentially anticipated (rather than surprise) recession is further addressed in the Supplementary Appendix.

\]

where \( h_j, u_j, k_j, j \in \{ a, n \} \) denote the demand for high-skill labor, low-skill labor and capital, respectively, of old and new firms; \( h_0, k_0 \) denote the demand for high-skill labor and capital of firms adopting the new technology; \( u_{ms} \) is the demand for low-skill labor of the manual services representative producer; \( H_s, U_s, K_s \) denote respectively the amounts of high-skill labor, low-skill labor and capital used in the training process;

3) the law of motion \( G \) is consistent with individual decisions.

4. Parametrization

The model is parameterized to match features of the United States economy since the middle of the 1980s, the beginning of the job polarization era. One period is one year. Below, we explain how the parameters are picked and Table 1 summarizes their values.

**Business cycle shocks**
The persistence and the standard deviation of the business cycle shocks, $\rho_2 = 0.85$ and $\sigma_2 = 0.025$, are set to match the first order autocorrelation and the volatility of HP-filtered real GDP per capita.\textsuperscript{12} The persistence value is close to what is normally used in the RBC literature (Cooley and Prescott, 1995). The standard deviation $\sigma_2$ is somewhat larger than usual values. Since, in the model, there is no labor-leisure choice, larger fluctuations in exogenous productivity are necessary to match aggregate output volatility.\textsuperscript{13}

Preferences
The time discount rate $b$ is set to 0.96, which implies a 4% annual interest rate. The risk aversion $\gamma$ is 1.

Production sector
The returns to scale parameter for firms producing intermediates is set to $\alpha = 0.9$, consistent with the estimates of Basu and Fernald (1997). The capital share parameter is $\beta = 0.3$, consistent with aggregate data. The share of high-skill labor in the old production technology is set to $\mu_0 = 0.45$ to match the fraction of routine employment in total employment at the beginning of the job polarization era. For the new technology, $\mu_1 = 0.83$ in order to match the cross-sectional dispersion in routine wage share in the total wage bill across intermediates producing firms to the value found by Zhang (2015).\textsuperscript{14} The elasticity of substitution between the new and old goods in the production of consumption goods is 4, so that $\theta = 0.75$, close to the estimates of Hsieh and Klenow (2014) and Bernard et al. (2003). The elasticity of substitution between intermediates and manual services is 0.167, which implies $\epsilon = -5$, in line with estimates of Buera and Kaboski (2009) and Herrendorf et al. (2014). Productivity of manual services is set to $A_{ms} = 5.91$ in order to match the employment share of non-routine manual labor in 1985. Physical capital depreciates at the rate of $\delta_k = 0.1$. The adjustment cost parameter is set to $\chi = 0.25$ to match the volatility of private investment.

Training
Calibration of the training intensity is not straightforward. To the best of our knowledge, there are no readily available empirical estimates of an aggregate training function that combines low and high-skill labor together with physical capital. Perli and Sakellaris (1998) consider an RBC economy with a human capital sector. Their human capital production technology is similar to ours and we follow them by setting the capital share to $\beta_2 = 0.1$ and the elasticity of substitution between high and low-skill labor to $\frac{1}{1 + \rho_s} = 0.5$. The latter value implies that high-skill labor and low-skill labor are strong complements in the training sector. The relative weight of high-skill labor is set to $\mu_2 = 0.0076$ in order to roughly match the teacher-student ratio in post-secondary education.\textsuperscript{15} The productivity $s = 0.248$ is set to match the number of low-skill agents in the training process $U_t$ in the initial steady state to the fraction of the civilian noninstitutional population in post-secondary education in 1985. Finally, the skill depreciation rate is set to $\delta_n = 0.05$.\textsuperscript{16}

Technology adoption
An old firm attempting to adopt the new technology is successful with probability $\xi (k, h) = 1 - \exp(-\eta k^{1/\alpha}h^{1-\beta_2})$. As for the earlier production technology, we set the capital intensity to $\beta_0 = 0.3$. The parameter $\eta > 0$ governs the importance of capital and high-skill labor for the technology adoption. If $\eta$ is large, then only a few workers and small amounts of capital are required to get the transition probability close to its maximum level of 1. On the contrary, a small value of $\eta$ implies a large demand for high-skill labor and capital among adopting firms. Thus, smaller $\eta$’s are associated with larger adoption costs. We set $\eta = 1.5$. Along the transition path, the resulting probability of successful technology adoption is around 0.33.\textsuperscript{17}

Technological progress
The decision of the firms whether to adopt the new technology or not depends on the gap between $A_0$ and $A_n$. $A_0$ is normalized to 1, while the evolution of $A_n(t)$ is parameterized as follows

$$A_n(t) = \begin{cases} 
0, & t < T_{start}, \\
A_0 + (\bar{A}_n - A_0) \frac{1 - \exp\left(-\frac{T_{finish} - T_{start}}{t_{finish} - t_{start}}\right)}{1 - \exp(-1)}, & t \in [T_{start}, T_{finish}], \\
\bar{A}_n, & t > T_{finish}.
\end{cases}$$

\textsuperscript{12} We match the moments of the initial steady state of the economy with their data counterparts between 1947 and 1985. Recall that the job polarization era, associated in our model with the arrival of the new technology, started around the mid 1980s, as argued by JFS.

\textsuperscript{13} As discussed in Footnote 11, the model is solved assuming perfect foresight. All shocks are therefore completely unanticipated and the value of $\sigma_2$ does not affect the impulse response functions directly. The value of $\sigma_2$ does however matter for the calibration of other parameters of the model.

\textsuperscript{14} Zhang (2015) sorts firms based on this characteristic and finds that the spread between the highest and the lowest quantiles is 0.37. In our model, there exists a trivial cross-section of firms among intermediates producers, with old firms having a higher routine wage share. $\mu_0 = 0.83$ implies that the difference in the routine wage share between new and old firms is close to 0.37. This value stays almost constant along the transition path.

\textsuperscript{15} According to the National Center for Education Statistics, this ratio was slightly below 6% in the 1980s and has increased to 7.6% by the 2010s. $\mu_1$ is set so that in the initial steady state $\frac{\mu_1}{\mu_0} = 0.07$. Due to the absence of reliable data, we ignore other forms of training besides higher education. However, as argued by Perli and Sakellaris (1998), higher education is responsible for up to 90% of total investment in human capital.

\textsuperscript{16} In the model $\delta_n$ can be interpreted as the retirement rate, which is currently around 3% in the US. One can assume that every period a fraction $\delta_n$ of the total labor force $L$ retires and is immediately replaced by low-skill workers. At the same time, $\delta_n$ should include the rate of skill obsolescence. Existing literature estimates the depreciation rate of human capital. Despite substantial variation, $\delta_n = 0.05$ is close to what is normally found (Heckman, 1976 and Mincer and Odeg, 1962).

\textsuperscript{17} Consistent with this number, Brynjolfsson et al. (1994) and Brynjolfsson and Hitt (2003) find that it normally takes several years for a firm to fully adopt computer technology.
where $T_{\text{start}}$ denotes the arrival of the new technology (the mid 1980s in our case, corresponding to the start of the job polarization era in JS). Upon arrival, its productivity is $A_{n0}$ and it increases over time until it reaches $\hat{A}_n > A_{n0}$ by $t = T_{\text{finish}}$.

The shape of the $A_n(t)$ process is inspired by the literature on general-purposes technology (GPT). The initial impact of the new technology $A_{n0}$ can be modest. Later on, a sequence of smaller innovations enhances the productivity of the new technology. As a result, the technology reaches its peak $\hat{A}_n$ after a (potentially long) lag $T_{\text{finish}} - T_{\text{start}}$. This is typical of GPTs (e.g., Bresnahan and Trajtenberg, 1995, Helpman, 1998, Jovanovic and Rousseau, 2005).

In our baseline analysis, $A_{n0} = 0.1$. $\hat{A}_n = 1.5$. $T_{\text{finish}} - T_{\text{start}} = 75$. These parameters are chosen to match the trend in the non-routine cognitive employment share reasonably well. Our choice of $\hat{A}_n$ and $T_{\text{finish}} - T_{\text{start}}$ is not unique to achieve this. A longer/shorter progress with a higher/lower terminal value can match the same series. Since the goal of the paper is not to predict when the growth of $A_n(t)$ will stop, we do not take a strong stand on precise values of $\hat{A}_n$ and $T_{\text{finish}} - T_{\text{start}}$. Importantly, our results on interactions of routine-biased technological change with business cycles are unaffected if $T_{\text{finish}} - T_{\text{start}}$ and $\hat{A}_n$ are varied simultaneously to match the observed non-routine cognitive employment share.

5. Numerical results

This section presents our main numerical results. In Section 5.1, we discuss the transition from the old steady state to the new one induced by the arrival of the new technology. Section 5.2 describes the differential impacts of business cycles on the economy in the pre- and during transition periods. Finally, Section 5.3 investigates the interaction between the Great Recession and routine-biased technological change.

5.1. Transition paths

We begin by investigating how the arrival of the new technology affects the economy without business cycle shocks. The path for the exogenous process $A_n$ is shown in Fig. 3. The initial shock is small, representing the idea that a new fundamental technology is hardly productive right after its arrival. As the new technology gradually becomes better, $A_n$ increases and reaches its steady-state level after 75 years.

Fig. 4 shows how the introduction of the new technology affects the technology acquisition decision of the firms and the occupational choices decision of the workers. Over time, firms adopt the new technology as its productivity increases (left

---

18 Historically, new general purpose technologies took significant lengths of time to achieve their full potential. For example, David (1990) argues that electricity delivered a major economic boost only in the 1920s, 40 years after the first generating station came into being. Crafts (2004) finds a lag of almost 100 years for steam-related technologies. Using asset prices, Ward (2015) predicts that it will take around 50 years for the IT to be fully absorbed by the economy.
Since the new technology is relatively more skill-intensive, low-skill workers respond accordingly and start to train to acquire new skill (right panel). As a result, routine manual employment (low-skill workers employed in the intermediates production) declines. Since the two inputs in the final consumption bundle are complementary, when the productivity of intermediates go up, it is optimal also to increase output of manual services. Consequently, low-skill employment in manual services increases gradually (the dot-dashed curve in the right-hand panel of Fig. 4). The model is able to generate job polarization and, as is discussed in more details in Section 5.3, it does a fairly good job in explaining these patterns quantitatively.

Fig. 5 illustrates other aspects of the technology adoption process. The top-left panel shows how the production of consumption goods $Y_f$ evolves over time. Despite the positive technological surprise at $t = 0$, $Y_f$ does not respond immediately. For roughly 15 years $Y_f$ is almost unchanged and starts to grow only afterwards. This is due to the GPT nature of the new technology. The adoption of such a technology requires significant investment in reorganization of the workplace and in the accumulation of the required production factors. This is illustrated by the top-right and bottom panels of Fig. 5. The top-right panel shows the ratio of total adoption costs $Y_a$ to final output $Y_f$. We use two measures of $Y_a$. The first measure, $Y_{a,1}$, includes capital and high-skill labor rents in the training and adoption technologies. The second measure, $Y_{a,2}$, also takes into account forgone profits due to firms being in the restructuring stage.

$$Y_{a,1} = w_h(H_0 + H_1) + r(K_0 + K_1),$$

$$Y_{a,2} = Y_{a,1} + \frac{\partial Y_f}{\partial m_h} (\bar{m} - m_h - m_o).$$

The calibration implies that $Y_{a,1}$ becomes as high as 2.70% of $Y_f$ around year 30. Around the same time, unmeasured reorganization investment, captured in our model by foregone output due to old firms going through the adoption process, account for about 0.28% of $Y_f$. Notice that in the new steady state adoption costs are higher than in the initial steady state (1.43% vs. 0.98%). In the new steady state, the number of high-skill workers is higher and more training is therefore required.

The bottom panel of Fig. 5 further illustrates that the period after the arrival of the technology is marked by a diversion of resources away from the production of final good. The total mass of active firms and the overall number of workers in the production sector are shrinking for around 30 years (the dot-dashed and dashed lines, respectively). High-skill labor is required for the firms’ reorganization and training of low-skill workers. At the same time, low-skill workers start to train...
in larger numbers, which contributes to a drop in the labor force participation (the solid line) and to an increase in school enrollment.\textsuperscript{21} These two phenomena have been visible in the U.S. data for the last two decades.

In particular, the model predicts that the labor force participation drops by around 4 p.p. between 1985 and 2017, which is comparable to the number observed in the data (Fig. 1, left panel). The model predicts a steady decline in the labor force participation, while in the data it was growing until the late 1990s and plummeted afterwards. Since the paper abstracts from several important aspects (e.g., labor force participation among women, which was increasing until the late 1990s), it cannot match the whole dynamics of the series.

Over the same period, the model-implied school enrollment ratio increased from 6.9% in 1985 up to 10.2% in 2014. This is larger than in the data, where the ratio increased from 6.9% up to 8.2% (Fig. 1, right panel). There are two reasons why the model-implied increase is higher. First, in the model, schooling represents all types of training, including on-the-job training and various job training programs, while the data counterpart takes into account only formal higher education. Second, in the model all workers are either employed or in schools, and a decrease in the number of employed low-skill workers necessarily leads to an increase in the number of employed high-skill workers (with a time lag). This approach misses a recent increase in non-employment among low-skill workers (Cortes et al., 2014 and Cortes et al., 2016) that is unrelated to education.\textsuperscript{22} Demographic changes, such as population aging, might also play a role (Autor and Dorn, 2009).

In our model, job polarization is driven by two main forces. First, the number of low-skill workers goes down along the transition path. As a result, the supply of routine workers diminishes. Second, at each point in time, the propensity of a low-skill worker to take a routine job (i.e., a job in an old or a new intermediates producing firm) goes down. On the one hand, she is more likely to attend school. Conditional on not attending school, on the other hand, she is more likely to do a manual services job. Formally, the routine employment $R$ can be written as

$$R = U (1 - p_{sc} - p_{nrm}) .$$

where $U$ is the total supply of low-skill workers in the economy, $p_{sc}$ and $p_{nrm}$ are the probabilities that a low-skill worker is in the training process or employed in manual services. Change in routine employment $\Delta R$ therefore can be decomposed into a composition and a propensity effect,

$$\Delta R = \Delta U (1 - p_{sc} - p_{nrm}) - U \Delta (p_{sc} + p_{nrm}) - \Delta U (p_{sc} + p_{nrm}) .$$

Table 2 presents the decomposition of the overall decline in $R$ between changes in $U$, $p_{sc}$ and $p_{nrm}$.

The model implies that both the composition and the propensity effects are important for job polarization, with the latter force being more significant. This is consistent with the micro evidence provided by Cortes et al. (2014) and Cortes et al. (2016).

5.2. Business cycles

This section compares the responses of the economy to business cycle shocks before and after the introduction of the new technology. First we investigate the impact of an adverse $z$ shock to the economy along the transition path. Specifically, we consider a large (2.5 standard deviations) $z$ shock happening 23 years after the new technology arrival. Assuming that the technology arrived around 1985, the timing and the magnitude of the recession in the model corresponds to the Great Recession in the data. We then compare the outcome of this first experiment with the response of the economy to the same shock before the new technology was available.\textsuperscript{23}

The results are shown in Fig. 6. Before the arrival of the new technology, the training of workers is counter-cyclical (the dashed curves in panels (f)–(h)), as is typical of RBC models with human capital (e.g., Perli and Sakellaris, 1998). The

\begin{table}[ht]
\centering
\caption{Model-implied change in routine employment $R$ between 1989 and 2014. The years are chosen as in Cortes et al. (2016).}
\begin{tabular}{cccccc}
\hline
 & $R_{1989}$ & $R_{2014}$ & $\Delta R$ & Composition & Propensity & Interaction \\
 & & & & Schooling & NRM & \\
\hline
$R$ & 50.47\% & 38.61\% & $-11.86\%$ & $-5.18\%$ & $-3.96\%$ & $-3.49\%$ & $0.76\%$ \\
\hline
\end{tabular}
\end{table}

\textsuperscript{21} Recall that in the model the only labor force non-participants are low-skill workers in schools $U_t$.

\textsuperscript{22} Aguiar et al. (2017) emphasize the importance of video games, streaming television, and other recreational activities that became widely accessible thanks to the improvements in information and computer technologies for reducing the labor supply of young males.

\textsuperscript{23} The arrival of the new technology changes the structure of the production technology. In general, this can affect the economy’s response to business cycle shocks by itself. We verify that our results are driven by the interaction between the adoption decisions and the business cycle rather than by a different production technology. In the Supplementary Appendix we consider the impulse responses to the same $z$ shock in the new steady state when the economy has fully transitioned. We find that these responses are much closer to their pre-transition counterparts than to the ones observed along the transition path.
intuition is straightforward. During recessions, workers are relatively inefficient in production and the economy therefore uses these periods to accumulate human capital.

This process is however amplified along the transition path for two reasons. In addition to the mechanism highlighted above, the household understands that, since firms also use the recession to adopt the new technology, the future demand for high-skill workers will increase. Economic downturns are therefore a perfect period to train the workforce for this increased demand. The second reason is that training and adoption are intensive in different factors, namely low and high-skill labor, which complement each other in the production of intermediates. When firms start to adopt the new technology in recessions, they demand high-skill labor. This decreases the marginal productivity of low-skill workers who are in production, and some of them therefore move into training. It turns out that the training-adoption complementarity is the main driver behind the additional investment in human capital that is observed during the recession. As we show in the Supplementary Appendix, when $\eta$ is high and adoption does not require substantial resources, counter-cyclical reallocation of low-skill labor towards training is much closer to the pre-transition case.

In sum, an adverse productivity shock to the final good sector leads to a more active reallocation of factors during the technological transition than before the arrival of the new technology. In particular, panels (g) and (h) show that training...
is now absorbing more resources. Reallocation towards adopting firms (panel (i)), which is completely absent in the initial steady state, is responsible for roughly half of the additional drop in the total production employment (panel (f)).

Panels (j)–(l) of Fig. 6 illustrate the production and adoption decisions of the firms. Since the technology change requires a temporary halt in production, it is more attractive during economic downturns when profits are lower. Panel (k) shows that the mass of old firms drops by 3.5 p.p. as a result of the negative z shock. This drop leads to a lagged increase in the mass of firms operating the new technology, as shown in panel (j).

The counter-cyclical adoption and training incentives are mitigated by the consumption smoothing motives of the representative household. However, this effect turns out to be relatively small for conventional values of the intertemporal elasticity of substitution.
As a result of the increased technological adoption and additional workers training triggered by the recession, the drops in output, consumption and investment are all significantly more pronounced during the technological transition than before the arrival of the technology (panels (b)–(d) in Fig. 6).24

5.3. The Great Recession and routine-biased technological change

We now investigate whether the model can rationalize both the long-run trend in the employment shares induced by routine-biased technological change and the importance of recessions in generating job polarization. We use the same definitions and data sources as JS. Particularly, non-routine cognitive/non-routine manual/routine jobs in their definition correspond to high-skill/low-skill manual services/low-skill intermediates jobs in the model. Fig. 7 shows the results.

We consider the impact of a negative 2.5 standard deviation $z$ shock 23 years after the technology arrival for the model-implied employment shares. Again, given our timing, this shock corresponds to the Great Recession in the data.25 The top panel of the figure shows the employment share of high-skill (model) versus non-routine cognitive (data) workers. Since technological progress in our model favors the high-skill-intensive technology, the corresponding employment share is gradually growing, in line with the data. The recession induces more active training, resulting in an upward shift of the curve. Similarly, the employment share of low-skill workers in intermediates producing firms (bottom panel) is declining overall but with a sharp drop down during the downturn. Finally, low-skill services employment share (middle panel) stays almost constant for the first 15 years. Since intermediates and manual services are strong complements, during the initial transition stage, when the intermediates output is barely changed, it is optimal not to increase the manual services output as well. Later on, low-skill employment starts to grow.26

Recent empirical evidence (e.g., JS and Hershbein and Kahn, 2018) emphasizes the acceleration of the routine employment loss during the Great Recession. Fig. 8 takes a closer look at this phenomenon. In the data, the routine employment share dropped by 1.9 percentage points between 2007Q4 and 2008Q4.27 Thus, 15% of the overall drop observed between January of 1985 and April of 2017 happened during only 1 year, or 3% of the total time span. In the model, a 2.5 standard deviation negative $z$ shock implies a drop of 1.43 p.p., or nearly 75% of what is observed in the data. In the absence of the $z$ shock, the model-implied routine employment share would have declined by only 0.61 p.p. because of the gradual transition between the steady states. The model is therefore able to replicate a substantial fraction of the routine employment loss during the Great Recession. At the same time, it implies that the effect of the Great Recession was to speed up, rather than cause, the decline in routine employment, since by the year 2012 the model-implied routine shares in the model both with and without the $z$ shock essentially coincide with the empirically observed value at just over 44%.

\footnote{In Supplementary Appendix we verify that recessions during technological transitions are still deeper, even after adjusting the output measure for training and adoption costs.}

\footnote{The size of the shock is picked in order to match the almost 10% drop in output during the Great Recession (Fajgelbaum et al., 2017).}

\footnote{The model does not match the increase of the non-routine manual employment share during the Great Recession. A negative TFP surprise induces reallocation of high-skill workers towards adoption and teaching. As a result, the intermediates production drops. Due to complementarity between intermediates and manual services, the marginal productivity of low-skill manual service workers declines as well and the planner therefore moves them to training.}

\footnote{We consider 1 year after the start of the Great Recession, since in the model the Great Recession is approximated by 1 large negative $z$ shock.}
Overall, Figs. 7 and 8 show that the model can match several important aspects of the job polarization phenomenon. First, the model is able to replicate the steady decline, since at least the start of the job polarization era, of the fraction of routine workers while, at the same time, replicating the increase in both non-routine cognitive and manual jobs. To do so, the model relies only on changes in the \( A_n \) process and on the complementarity between intermediates and manual services. Second, the model is also able to generate the acceleration of the job polarization process during recessions and, specifically, during the Great Recession. The counter-cyclical restructuring incentives are responsible for these rapid movements during economic downturns.

6. Concluding remarks

In this paper, we analyze the interaction between routine-biased technological change and business cycles. Since economic downturns are periods of low opportunity costs, they are used by firms to optimize their production technology and by workers to adjust their skill set to a changing economic environment. Restructuring incentives are enhanced during technological transitions, associated with higher than usual demand for new skills. As a result, recessions during transitions are marked by a sizable scarcity of factors in the final good production. At the same time, routine-biased technological change is accelerated, consistent with the recent empirical evidence.

The paper provides a theoretical rationale for two major features of job polarization. First, the fraction of routine workers has been declining since at least the mid-1980s, while both non-routine cognitive and non-routine manual employment shares have been growing. Second, job polarization is concentrated in recessions. In our model, a gradual technology adoption generates the trend, while large downturns speed up the transition due to counter-cyclical restructuring incentives.

The model can be extended along several important directions. First, we assume that low-skill workers can switch between routine and non-routine manual jobs without any frictions. Although costs of training for a manual services job are presumably much smaller than for a non-routine cognitive one, they are not zero. A more detailed modelling of occupation choice might help to explain the increase in the non-routine manual employment share during the Great Recession. In particular, time to train for a manual services job is likely to make this process counter-cyclical. Thus, model-implied non-routine manual employment share should exhibit an uptick during downturns.

Furthermore, as discussed in Section 5.1, one could allow workers to permanently stay out of the labor force, for example, by introducing a home production sector. It would be interesting to investigate, both theoretically and empirically, how routine-biased technological change and recessions along the transition path affect labor adjustments along this margin. Another potential direction would be to enrich the model with a labor-leisure choice. If the value of leisure is affected by the new technologies, as suggested by Aguier et al. (2017), then the model could rationalize declining labor force participation, as well as job polarization.
